

INTEGUMENT (= skin or cutis)

The integument is the covering of body. It lies in direct contact with the external environment. Hence, it is modified in various ways in different groups of vertebrates.

It consists of

- 1) Epidermis - outer layer
- 2) Dermis - deep-lying layer.

Beth epidermis and dermis may be involved in the skin derivatives such as scales, hair, feathers, bony plates, various glands etc.

General structure of Skin

1) Epidermis - outer, thin layer, of ectodermal origin which forms a continuous epithelium over the entire body. This layer may contain sensory cells, light organs etc.

Divided into two sub layers:

- a) an outermost layer of dead cells called stratum corneum
- b) inner layer is Malpighian layer of stratum germinativum.
The cells of Malpighian layer give rise to the cells of epidermis. The epidermis generally does not have blood and nerve supply.

2) Dermis - lies immediately beneath the epidermis. It is largely composed of fibrous connective tissue and contains different varieties of cell elements. The dermis is richly supplied with blood vessels, lymphatic and nerves.

Integument - in different groups of vertebrates

The integument presents many different conditions in different groups of vertebrates -

In Cyclostomes (Lamprey and hag fishes)

Integument is many layered. The innermost layer is the Malpighian layer which meets up with a thin basement membrane.

In lamprey - the outermost layer of the epidermis is thin cuticle. Epidermis contains several granular and club-shaped secretory cells. The upper layer of the epidermal cells below the cuticle is modified calcareous cells.

In Myxine - epidermis contains bladder cells. The outer most layer of the epidermis is that of mucus or slime. Dennis in lamprey is stratified into thick and very thin layer of pigment cells.

② In fishes - the skin of fishes is rich in mucous glands which form a protective mucus coat over the skin. Some elasmobranchs and a number of teleosts have poison glands usually associated with the fine spines of the fins. Light producing organ photophores may also be present, particularly in deep sea dwelling fishes. Stratum corneum is absent in fishes.

(i) In elasmobranchs - epidermis is composed of many layers of epithelial cells, interspersed mucus gland. The tips of the placoid scales extend out throughout the epidermis.

Dermis has following three layers.

(i) Stratum laxum - outer layer below the epidermis; free from fibers.

(ii) Stratum compactum - middle layer of the dermis, consists of laminated fibers.

(iii) Subcutaneous layer - innermost layer, contains a network of fine fibers.

In teleost - Epidermis is stratified and contains abundant mucous glands. It may be unicellular or multicellular. Granular secretory and club cells are also found in epidermis. The granular cells originate a large Leydig's cell in club cells from the intercellular matrix of the matrix of the epidermis. The epidermis is dotted by sensory organs called peal organs.

Dermis is composed of fibrous connective tissue and contains network of blood capillaries. It can be divided into an inner layer. Outer is composed of loose areolar tissue and contains the scales surrounded by scattered fat cells and pigment cells. Inner layer is densely fibrous. In dermis of bony fishes encloses the scales lodged in pouches.

The dermis of many bony fishes contains sensory colours of chromatophores and granules containing iridophores (responsible for the silver color of many fishes).

(3) In Amphibians - Most are frequently slimy skin. stratum corneum, finely apparent in the group. It is apparently due to transitory hair.

The epidermis has many layers of cells.

In the adult - stratum germinativum

Outer most - stratum corneum.

In the tail stratum corneum is thicker. It may be thick. In epidermis possess sensory papillae. Below the epidermis is a thin basement membrane.

Dermis, relatively thin and is made up of two

layers - upper loose - stratum spongiosum and lower compact stratum compactum.

The pigment cells of chromatophores are found in the upper portion of the dermis. Buried in the dermis are found mucous and poison glands which secrete mucus.

epidermis. The dermis is richly supplied with blood vessels. The integument of amphibia does not have scales except in the Gymnophiona, where skin is thick and contains groups of dermal scales.

(4) In Reptiles - It's thick, dry and covered with keratinized epidermal scales or bony plates of dermal origin. It has almost no glands.

The epidermis is many layers with well developed stratum corneum. The epidermal glands occur only in a few cases such as few oil glands in lizards and cloacal scent glands in alligators.

epidermis covering is periodically shed (ecdysis) in lizards and snakes.

Dermis is thick and has an upper and lower layer. The upper layer contains abundant chromatophores in snakes and lizards. Lower layer is composed of connective tissue fibers.

(5) In Birds - It's thin, dry, loose fitting, devoid of glands. The oil glands are mucous glands, just above the tail. The skin is covered with feathers.

The epidermis has a basal malpighian layer and an outer stratum corneum. It's delicate, except on shanks and feet where it's thick and forms epidermal scales. Epidermis has great ability to produce keratin, responsible for the formation of feathers and scales.

Dermis is compact and is made up of connective tissue, muscle fibers, nerve fibers, blood capillaries at tail cells, no pigment cells. It is most occurs only in feathers and scales.

(6) In Mammals - Thick, elastic and waterproof. It has an outer layer of flattened keratinizing dead cells, the stratum corneum. The sequence of cell layers in epidermis is as follows: —

- ① Basal, stratum germinativum, which rests upon a basement-membrane.
- ② stratum spinosum (iii) stratum granulosum
- ④ stratum lucidum ⑤ stratum corneum - outer layer of dead keratinized cells.

Mucus glands are absent in the epidermis of mammals. The dermis is greatly developed in mammals. It is made up of loose connective tissue, blood vessels and nerves.

The upper part of the dermis just below the epidermis contains dense reticular fibers parallel to the surface. This layer is called papillary layer.

In the dermis the following structures of epidermal origin are found:

- ① Hair follicle - formed by the penetration of epidermis into dermis. It lodges the hair papilla from which grows the hair.
- ② Sebaceous gland - flask shaped gland which opens into the hair follicles. These secrete only an oily substance Sebum.
- ③ Sweat gland - these are small coiled tube like glands which open through pores on the surface of the skin.
